

CSE 100 Notes

Advanced Data Structures

Fall 2021

Taught by Professor Niema Moshiri

Table of Contents

1	A Brief Introduction	1
1.1	Data Structures vs. Abstract Data Types	1
2	Introduction to C++	3
2.1	Data Types	3
2.2	Strings	3
2.2.1	Representation	3
2.2.2	Mutability	3
2.2.3	Concatenation	3
2.2.4	Substring Method	4
2.3	Comparing Non-Primitive Objects	4
2.4	Variables	4
2.4.1	Initialization	4
2.4.2	Narrowing	5
2.4.3	Variable Declaration	5

1 A Brief Introduction

In this course, we will primarily be building off of our prior knowledge of data structures (CSE 12). In particular, we will:

- Analyze data structures for both time and space complexity.
- Describe the strengths and weaknesses of a data structure.
- Implement complex data structures correctly and efficiently.

1.1 Data Structures vs. Abstract Data Types

When talking about data, we often hear about data structures and abstract data types.

Data Structures (DS)	Abstract Data Type (ADT)
<p>Data structures are collections that contain:</p> <ul style="list-style-type: none"> • Data values. • Relationships among the data. • Operations applied to the data. <p>It also describes how the data are organized and how tasks are performed. So, a data structure defines every single detail about anything relating to the data.</p>	<p>Abstract data types are defined primarily by its <u>behavior</u> from the view of the <u>user</u>. So, not necessarily how the operations are done, but rather what operations it must have from a completely abstract point of view.</p> <p>Specifically, it describes only what needs to be done, not how it's done.</p>

Consider the `ArrayList` (DS) vs. the `List` (ADT).

- A `List` will most likely have the following operations:
 - **add**: Adds an element to the list.
 - **find**: Does an element exist in the list?
 - **remove**: Remove an element from the list.
 - **size**: How many elements are in this list?
 - **ordered**: Each element should be ordered in the way we added it. For example, if we added 5, and *then* added 3, and *then* added 10, our list should look like: [5, 3, 10].

Of course, as an abstract data type, `List` isn't going to define how these operations work. It just lists all operations that any implementing data structure must have. In other words, we can think of `List`, or any abstract data type, as a *blueprint* for future data structures.

- An `ArrayList` is simply an array that is expandable. It is internally backed by an array. So, we can perform the following operations:
 - We can **add** an element to the `ArrayList`. In this case, we add the element to the next available slot in the array, expanding the array if necessary.
 - We can **find** an element in the `ArrayList`. In this case, we can search through each slot of the array until we find the array or we reach the end of the array.
 - We can **remove** an element from the `ArrayList`. In this case, we can simply move every element after the specified element back one slot.
 - We can get the **size** of the `ArrayList`. In this case, this is as simple as seeing how many elements are in this `ArrayList`.
 - And, we know that the `ArrayList` is **ordered**. In this case, this is already done via the **add** and **remove** methods.

Notice how **ArrayList** specifies how each operation defined by **List** works. In this sense, we say that **ArrayList** essentially implements **List** because we need to define *how* the tasks defined by **List** are performed.

So, the key takeaways are:

- An abstract data type (in our case, **List**) specifies what needs to be done without specifying how it's done.
- A data structure (in our case, **ArrayList**) actually defines **how** the data is organized, how the different operations are performed, and how exactly everything is represented.

2 Introduction to C++

Here, we will talk about C++, the programming language that we will use in this course.

2.1 Data Types

First, we'll compare the data types in Java and C++.

Data Type	Java	C++
byte	1 byte	1 byte
short	2 bytes	2 bytes
int	4 bytes	4 bytes
long	8 bytes	8 bytes
long long		16 bytes
float	4 bytes	4 bytes
double	8 bytes	8 bytes
boolean	Usually 1 byte	Usually 1 byte 1 byte
bool		
char	2 bytes	

It should be mentioned that:

- In Java, you can only have signed data types.
- In C++, you can have both signed and unsigned data types.
- `boolean` (Java) and `bool` (C++) are effectively the same thing: they represent either `true` or `false`.

2.2 Strings

There are some major differences between strings in Java and C++, which we will discuss below.

2.2.1 Representation

In Java, strings are represented by the `String` class. In C++, strings are represented by the `string` type.

2.2.2 Mutability

Strings in Java are immutable. The moment you create a string, you won't be able to modify them. The only way to change a string variable is by creating a new string and reassigning them.

In C++, strings are actually mutable. You can modify strings in-place.

2.2.3 Concatenation

In Java, you can concatenate any type to a string. For example, the following is valid:

```
String a = "this is a string" + 123;
```

In C++, you can only concatenate strings with other strings. So, if you wanted to convert an integer (or any other type) to a string, you would have to *first* convert that integer to a string (or use a string stream).

2.2.4 Substring Method

In Java, we can take the substring of a string using the `substring` method. The method signature is:

```
String#substring(beginIndex, endIndex);
```

In C++, we can take the substring using the `substr` method. The method signature is:

```
string#substr(beginIndex, length);
```

An important distinction to make here is that Java's `substring` method takes in an **end index** for the second parameter, whereas C++'s `substr` method takes in a **length** for the second parameter.

2.3 Comparing Non-Primitive Objects

Suppose `a` and `b` are two non-primitive objects.

In Java, if we want to compare these two objects, we have to make use of the methods:

```
a.equals(b)
a.compareTo(b)
```

If we tried using the relational operators like `==` or `!=`, Java would compare the memory addresses of the two objects, which is often something that we aren't looking for.

In C++, even if `a` and `b` are objects, we can make use of the relational operators:

```
a == b      a != b
a < b       a <= b
a > b       a >= b
```

This is done through something called **operator overloading**, where we write a custom class and define how these operators should function.

2.4 Variables

Now, we will briefly discuss how variables function in both C++ and Java.

2.4.1 Initialization

In Java, variable initialization is **checked**. Consider the following code:

```
int fast;
int furious;
int fastFurious = fast + furious;
```

Because `fast` and `furious` aren't initialized, the Java compiler will throw a compilation error.

In C++, variable initialization is **not checked**. Consider the same code, which will compile:

```
int fast;
int furious;
int fastFurious = fast + furious;
```

Here, this would result in **undefined** behavior.

2.4.2 Narrowing

In Java, if we have a higher variable type and then try to cast this type to a smaller type, we would get a compilation error. Consider the following code:

```
int x = 40_000;
short y = x;
```

This code would result in a compilation error. If we didn't want a compilation error, we would have to explicitly *cast* the bigger variable type to the smaller type. The following Java code would compile just fine:

```
int x = 40_000;
short y = (short) x;
```

In C++, no compilation error would occur; that is, the following code would compile:

```
int x = 40_000;
short y = x;
```

What would actually happen is that **x** would get **truncated** when it is assigned to **y**, resulting in integer overflow.

2.4.3 Variable Declaration

In Java, variables **cannot** be declared outside of a class. The following Java code would result in a compile error:

```
// MyClass.java

int meaningOfLife = 42;
class MyClass {
    // some code
}
```

In order for this to compile, you have to put variable declarations inside the class space (as an instance variable) or in a method inside a class (as a local variable).

In C++, variables **can** be declared outside of a class. The following C++ code would compile completely fine:

```
// MyClass.cpp

int meaningOfLife = 42;
class MyClass {
    // some code
}
```

Here, `meaningOfLife` is a **global variable**. Anything in this file can access this variable. In general, it is considered poor practice to use global variables except in cases of constants.
